Ultrahigh-speed distributed Brillouin reflectometry

Yosuke Mizuno[1], Neisei Hayashi[2], Hideyuki Fukuda[3], Kwang Yong Song[4] and Kentaro Nakamura[1]

Optical fibre sensors based on Brillouin scattering have been vigorously studied in the context of structural health monitoring on account of their capacity for distributed strain and temperature measurements. However, real-time distributed strain measurement has been achieved only for two-end-access systems; such systems reduce the degree of freedom in embedding the sensors into structures, and furthermore render the measurement no longer feasible when extremely high loss or breakage occurs at a point along the sensing fibre. Here, we demonstrate real-time distributed measurement with an intrinsically one-end-access reflectometry configuration by using a correlation-domain technique. In this method, the Brillouin gain spectrum is obtained at high speed using a voltage-controlled oscillator, and the Brillouin frequency shift is converted into a phase delay of a synchronous sinusoidal waveform; the phase delay is subsequently converted into a voltage, which can be directly measured. When a single-point measurement is performed at an arbitrary position, a strain sampling rate of up to 100 kHz is experimentally verified by detecting locally applied dynamic strain at 1 kHz. When distributed measurements are performed at 100 points with 10 times averaging, a repetition rate of 100 Hz is verified by tracking a mechanical wave propagating along the fibre. Some drawbacks of this ultrahigh-speed configuration, including the reduced measurement accuracy, lowered spatial resolution and limited strain dynamic range, are also discussed.

INTRODUCTION

Brillouin scattering[1] is regarded as one of the most promising principles of fibre-optic sensing in terms of the feasibility it affords for measurements of strain and temperature distribution. The Brillouin-based distributed sensors developed so far can be classified into two types: 'analysis' in which two light beams are injected into both ends of a fibre under test (FUT) and 'reflectometry' in which a light beam is injected into only one end of an FUT. The former category includes Brillouin optical time-domain analysis (BOTDA)[2–12], Brillouin optical frequency-domain analysis (BOFDA)[13–16] and Brillouin optical correlation-domain analysis (BOCDA)[12,17–25], whereas the latter category includes Brillouin optical time-domain reflectometry (BOTDR)[26–30] and Brillouin optical correlation-domain reflectometry (BOCDR)[31–37]. For each technique, a number of different configurations have been proposed in order to improve the sensing performance in terms of spatial resolution, measurement range, signal-to-noise ratio (SNR), sampling rate, repetition rate, strain and temperature sensitivity, strain dynamic range, system simplicity and cost efficiency. Here, we focus on Brillouin sensors with a high sampling (or repetition) rate for distributed dynamic strain measurement.

To date, extremely high sampling rates have been achieved in BOTDA[3–11] and BOCDA[19,20,25]. In particular, Voskoboinik et al.[3] have proposed the idea of using multiple pumps and probes in BOTDA to avoid time-consuming frequency sweeping, thus leading to a potential increase in measurement speed at the expense of frequency granularity. Furthermore, inspired by the idea of Bernini et al.[4], Peled et al.[5] have developed slope-assisted BOTDA, which interrogates the FUT with a single frequency located at the middle of the slope of the local Brillouin gain spectrum (BGS), thereby enabling a single pump pulse to sample the strain distribution along the full length of the FUT. By synthesising an adaptable probe wave, an FUT with an arbitrary Brillouin frequency shift (BFS) distribution can be interrogated, though the strain dynamic range is limited by the size of the linear section of the BGS. Peled et al.[6] have also demonstrated dynamic BOTDA measurements by implementing the fast switching of optical frequency using high-performance arbitrary-waveform generators, though the measurement time becomes longer as the length of the FUT increases. In addition, Taki et al.[7] have proposed the use of cyclic pulse coding based on quasi-periodic bit sequences in BOTDA for an FUT with a length on the order of kilometres. This configuration allows for real-time decoding, resulting in a substantial reduction in the number of averages required to guarantee an acceptable SNR. Performance improvements for these distributed dynamic sensors based on BOTDA are still being aggressively studied[8–11].

As for BOCDA, Song et al.[19] have achieved a 1 kHz sampling rate at a single location using a time-division pump-probe generation scheme

with optimised temporal gates and an unbalanced Mach–Zehnder delay line. By using differential frequency modulation, they have additionally demonstrated a distributed measurement over a 100-m-long FUT at a 20-Hz repetition rate with a spatial resolution of 80 cm[20]. Random accessibility with a 5-kHz sampling rate has also been demonstrated by the employment of a high-speed lock-in amplifier[25]. In this manner, only analysis systems based not on spontaneous but on stimulated Brillouin scattering (SBS) have been exploited to acquire Brillouin signals on a real-time basis with sub-metre spatial resolution.

In general, SBS is induced by a so-called pump-probe configuration, which poses one major problem. This configuration requires the pump and probe lights to be injected into both ends of the FUT, which is not convenient for practically embedding the sensors into materials and structures; furthermore, the measurement can no longer be performed when extremely high loss or breakage occurs at a point along the FUT. Some quasi-one-end-access configurations[16,21,22] have been developed by exploiting the Fresnel reflection at the open end of an FUT (cut perpendicularly to the fibre axis for high reflection, with a mirror or a small fibre loop sometimes being equipped), but they cannot perfectly overcome the measurement difficulties associated with a breakage point.

Against this background, it is of paramount importance to develop distributed Brillouin sensing technology that simultaneously provides a high sampling/repetition rate, intrinsically one-end-access interrogation, and high spatial resolution. BOTDR does not seem to be suitable because the spontaneous-Brillouin-scattered signal generated by incident optical pulses is so weak that the signal needs to be integrated numerous times[26–30].

In this work, we describe a new configuration for BOCDR that satisfies these three requirements simultaneously. BOCDR is known to be an intrinsically one-end-access sensing technique with high-spatial resolution, but its highest sampling rate reported so far was lower than 20 Hz. Here, using a voltage-controlled oscillator (VCO), the frequency sweeping for acquiring the BGS is performed at high speed without using the inherent sweeping function of an electrical spectrum

analyser (ESA), which is used only to detect the signal power at a fixed frequency component. The BGS is then approximated by a sinusoidal waveform, and the BFS is converted into its phase delay, which is further converted into a voltage for direct measurement. When a single-point measurement is performed at an arbitrary position, a maximal strain sampling rate of 100 kHz is experimentally verified by detecting dynamic strain at 1 kHz. When distributed measurements are performed at 100 points with 10 times averaging, a repetition rate of 100 Hz (corresponding to the maximal sampling rate (100 kHz) divided by the number of points and the number of averages) is then proved to be feasible by tracking a propagating mechanical wave. This ultrahigh-speed configuration functions at the sacrifice of the deteriorated measurement accuracy, lowered spatial resolution, and limited range of measurable strain, which are fully discussed.

MATERIALS AND METHODS

BOCDR[31,32] is known as a distributed sensing technique with intrinsic one-end accessibility and high spatial resolution. Its operating principle is based on the correlation control of continuous lightwaves in a self-heterodyne scheme. In other words, the pump light and the reference light (instead of the probe light used in BOCDA) are sinusoidally frequency-modulated at f_m, producing periodical 'correlation peaks'[38] in the FUT. The measurement range d_m, determined by the interval between the correlation peaks, is inversely proportional to f_m, as follows[32]:

$$d_m = \frac{c}{2nf_m} \qquad (1)$$

where c is the velocity of light in a vacuum and n is the refractive index of the fibre core. By sweeping f_m, the correlation peak, i.e. the sensing position, can be scanned along the fibre to acquire a BGS or BFS distribution. The spatial resolution Δz is given by[32]:

$$\Delta z = \frac{c\Delta \nu_B}{2\pi nf_m\Delta f} \qquad (2)$$

Figure 1 Configuration of ultrahigh-speed BOCDR. Experimental setup. EDFA, erbium-doped fibre amplifier; IF, intermediate frequency; LO, local oscillator; RF, radio frequency.

where $\Delta\nu_B$ is the Brillouin bandwidth (~30 MHz in silica single-mode fibres (SMFs)) and Δf is the modulation amplitude of the optical frequency. Note that Δf is practically limited to one half of the BFS of the FUT because of the noise caused by the Rayleigh scattering[31,32]. To date, the highest sampling rate including data acquisition to the computer was 19 Hz[33], and was limited by the sweeping speed of an ESA.

The experimental setup of the newly configured BOCDR is schematically shown in Figure 1. The fibre-optic parts were similar to those in a conventional setup[35]; a polarisation scrambler was employed in the pump path (see Supplementary Information for details). The heterodyned Brillouin signal was converted into an electrical signal using a photo detector (PD). The key point of high-speed BGS acquisition is the conversion of the BGS from the frequency domain to the time domain (Figure 2a). The PD output was mixed with the output of a VCO, the frequency of which was repeatedly swept over a range of several hundred megahertz using a function generator, resulting in the BGS scanned in the frequency domain. The power at a fixed frequency component (carefully chosen) of the mixed signal was then output from the ESA using a so-called zero-span mode, which repeatedly provided the BGS in the time domain. The BGS acquisition (determined by the repetition rate of the VCO) must be slower than the calculation time required for the BFS derivation from the BGS, and therefore we developed a method for simultaneously deriving the BFS and the BGS. The basic concept of the subsequent signal processing is shown in Figure 2b. The ESA output, which can be regarded as the BGS in the time domain, was approximated by a one-period sinusoidal waveform using a band-pass filter (BPF) with the same central frequency as the repetition rate of the VCO. At this stage, the BFS was in one-to-one correspondence with the phase delay of the sinusoidal waveform (at the expense of the limited range of measurable strain; only a phase delay smaller than 180° can be properly detected). The phase delay was then converted into a quasi-DC voltage using an electrical amplifier (AMP), an exclusive-OR (XOR) logic gate, and a low-pass filter (LPF), and was finally input to the computer via a sound board and monitored using a
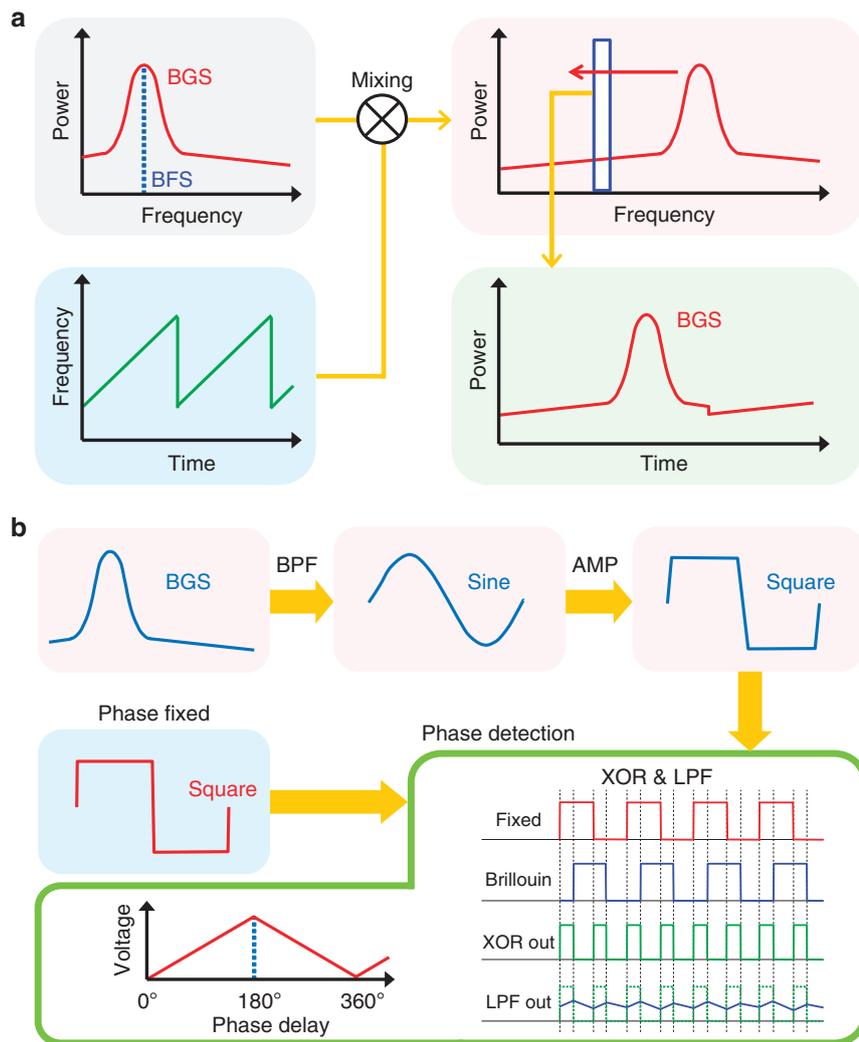

Figure 2 Principles of high-speed acquisition of BGS and BFS. (**a**) BGS acquisition. By mixing with a frequency-swept microwave, the BGS originally observed in the frequency domain can be obtained in the time domain at high speed. (**b**) BFS acquisition. The BGS is approximated by a one-period sinusoidal waveform and rectified. Its phase delay, which corresponds to the BFS, is then detected using an XOR logic gate and an LPF. The output voltage is in one-to-one correspondence with the phase delay in the range from 0 to 180°.

virtual oscilloscope triggered by the repetition frequency for the distributed measurement.

RESULTS AND DISCUSSION

Operation confirmation

First, the VCO operation with a BFS sampling rate of 100 kHz was confirmed (an even higher sampling rate was achievable if the SNR deterioration was admitted). When the frequency-control voltage was linearly applied to the VCO (blue line in Figure 3a), the output frequency was distorted (blue curve in Figure 3b) because of the nonlinear frequency dependence on the applied voltage. Therefore, we applied a pre-distorted voltage (red curve in Figure 3a) and obtained the linear output frequency (red line in Figure 3b). The output frequency was swept from 2.17 to 2.53 GHz, which was set to be sufficiently lower than the BGS (~10.8 GHz) of a silica SMF. If this frequency were close to the BGS, the differential component of their mixed signal would be located near DC and overlapped by its own folded spectrum, resulting in a significantly deteriorated SNR.

Next, we verified that the phase delay and the final DC voltage were in one-to-one correspondence with the applied strain. A 12.8-m-long silica SMF (composed of a 0.8-m-long pigtail of an optical circulator connected to a 12-m-long SMF using an FC/APC adaptor) was used as the FUT. Strains of up to 0.30% were applied to a 0.4-m-long section (6.6–7.0 m away from the circulator) (Figure 4). The open end was cut at an angle of 8° in order to suppress the Fresnel reflection. The modulation frequency f_m was set to 7.222 MHz, with a correlation peak located at the midpoint of the strained section. The measurement range d_m was calculated to be 14.2 m according to Equation (1). The modulation amplitude Δf was set to 0.35 GHz, resulting in a theoretical spatial resolution Δz of ~0.38 m from Equation (2). The ratio of the measurement range to the spatial resolution was ~37, which can be extended to ~570 simply by increasing Δf to half of the BFS, i.e. ~5.4 GHz (the Δf values were kept relatively low to avoid damage to the laser, which was not designed for large-amplitude modulation use). The 64th correlation peak was used, and the room temperature was 18 °C.

The raw and sinusoidally approximated BGSs with and without 0.07% strain are shown in Figure 5. The vertical axis was normalised so that the maximal and minimal powers of each spectrum became 1 and − 1, respectively. Averaging was performed 10 times. The peaks of the raw BGSs, i.e. BFSs, were not completely the same as those of the

approximated BGSs. This is natural considering that the approximation was performed using the whole shape of the BGS, and the strain can still be correctly detected so long as the actual BFS and the peak of
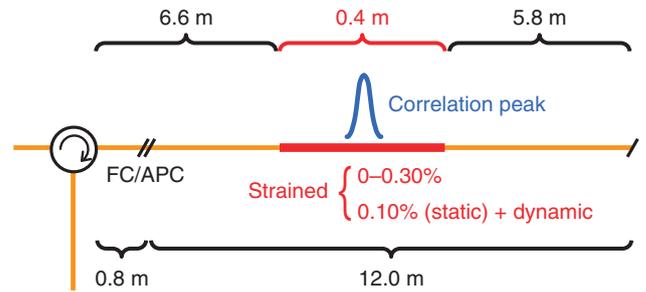

Figure 4 Structures of FUT. Strains of up to 0.30% were applied to a 0.4-m-long section of a 12.8-m-long silica SMF, which was composed of a 0.8-m-long pigtail of an optical circulator connected to a 12-m-long SMF using an FC/APC adaptor.
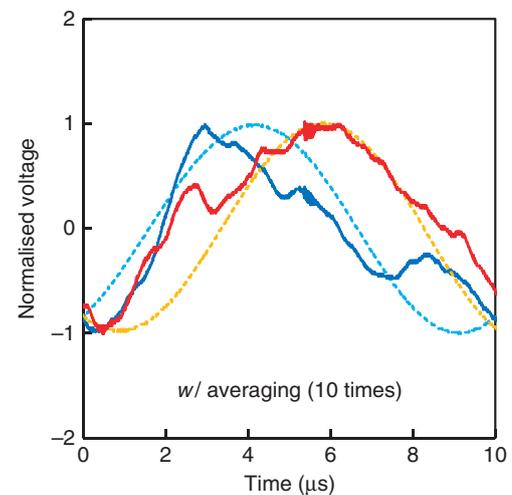

Figure 5 Normalised raw and sinusoidally approximated BGSs. The red and blue solid curves indicate the raw BGSs with and without 0.07% strain, respectively; whereas the orange and aqua dashed curves are the approximated BGSs with and without 0.07% strain, respectively. Averaging was performed 10 times.
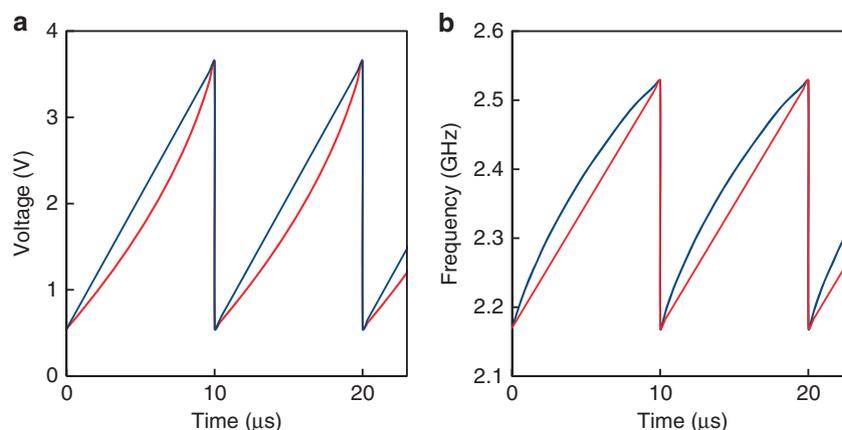

Figure 3 VCO operation with a BFS sampling rate of 100 kHz. (**a**) Linearly applied voltage (blue) and pre-distorted applied voltage (red). (**b**) Output frequencies when the voltage was applied in linear (blue) and pre-distorted (red) manners.

the approximated BGS are in one-to-one correspondence (to be verified in the following paragraph). The raw and sinusoidally approximated BGSs with no averaging and 100 times averaging are also shown in Supplementary Fig. S1a and S1b, respectively. As the average number of times increased, the SNR was improved, which indicates that a 100 kHz sampling rate can be obtained if a low SNR is admitted.

The strain dependence of the normalised BGS approximated by a one-period sinusoidal waveform is then shown in Figure 6. Averaging was performed 10 times. The phase was delayed with increasing strain, but the dependence was not completely linear. The phase delay dependence on strain of up to 0.20% (Figure 7a) was almost linear with a slope of 952 degrees/% (calculated excluding the data at >0.20%, which deviated from the linear trend). Here, to evaluate the measurement accuracy, we displayed the error bars calculated at each strain as the standard deviations of 100 data plots. The possible error was not constant at different strains and was largest (+/−15.4°) at ~0.15% strain, because of the spectral noise structure unique to the

Figure 6 Strain dependence of the normalised BGS approximated by a one-period sinusoidal waveform. The spatial resolution Δz was 0.38 m, and the length of the strained section L_ε was 0.4 m. Averaging was performed 10 times.

ESA. In the worst case, the measurement error was approximately +/−10%. We admit that this value is not sufficiently low for accurate strain measurements, but this system is still useful in some relatively rough dynamic strain measurements.

The final DC voltage, i.e. the output from the LPF (cut-off frequency = 1.2 kHz) was also plotted as a function of applied strain (Figure 7b). The voltage increased linearly with increasing strain (slope = 3.2 V/%) and reached a maximum at ~0.2%, where the phase delay became 180°. At this stage, it decreased for strains beyond ~0.2%. The DC voltage was thus confirmed to correspond to the applied strain, but with a limited strain dynamic range.

Finally, we investigate the error of our phase-based detection, which is possibly induced by the modification of the BGS due to the irregular strain distribution in the vicinity of the correlation peak. In general, the BGS in the correlation-domain techniques consists of two spectral contributions: one is the sharp signal peak corresponding to the strain and the other is the sum of the noise substructure originating from all the other positions[23]. Therefore, the strain distribution at the positions near the correlation peak may modify the overall shape of the BGS, although the peak frequency is maintained. Figure 8 shows one of some extreme cases where large strains are applied near the correlation peak (refer to Supplementary Information for details), and one can see significant modification of the BGS. In order to quantify the possible error of the phase-based detection caused by such a 'neighbourhood effect', we performed some simulations using the method detailed in Ref. 24 with various strain distributions near the correlation peak. As detailed in Supplementary Information, we can conclude that if we allow an absolute error of +/−200 με (or +/−10 MHz), the spatial resolution is effectively lowered by ~3 times. It should be also noted that the drop in performance is dependent on the measurement parameters such as the frequency sweep range, FUT length, and maximal applied strain. This finding will be a universal guideline, which is useful not only for this method but also for the other spectral-shape-based methods such as slope-assisted BOCDR[37].

Demonstrations

The first demonstration was dynamic strain measurement. A 0.10% static strain was applied in advance to a 0.4-m-long section (6.6–7.0 m) of the 12.8-m-long silica SMF (Figure 4); the static strain was applied because it was difficult to stably apply dynamic strains to a

Figure 7 Phase delay and output DC voltage measured as functions of applied strain. (**a**) Strain dependence of the phase delay. The spatial resolution Δz was 0.38 m, and the length of the strained section L_ε was 0.4 m. Averaging was performed 10 times. The error bars were calculated at each strain as the standard deviations of 100 data plots. The slope in the range from 0 to 0.20% was 952 degrees/%. (**b**) Strain dependence of the output DC voltage. The slope in the range from 0 to 0.20% was 3.2 V/%.

non-strained section. Dynamic strains at 30 Hz, 100 Hz, 300 Hz and 1 kHz were then applied to the same section using a vibration generator, which makes it unnecessary to consider the neighbourhood effect discussed in the previous section. Averaging was performed 10

times. The other experimental conditions were the same as those for the operation confirmation described above. The measured temporal variations (deviation from the initial value) of the output voltage (Figure 9a–9d) indicate that the dynamic strains of up to 1 kHz were successfully detected, though the data at 1 kHz were somewhat distorted. The vibration amplitude, which is dependent on the vibration frequency, can be derived from Figure 7b; for instance, at 30 Hz, the applied strain ranges from 0.02% to 0.18%, corresponding to a vibration amplitude of 0.32 mm. This value was moderately consistent with the value directly measured by the laser Doppler velocimetry.

Subsequently, to demonstrate the system's capability for ultrahigh-speed acquisition of the strain distribution, we attempted to track the propagation of a mechanical wave[39] along the FUT. The structure of the FUT is depicted in Figure 9e, where a 3.2-m-long section (6.0–9.2 m) was tightly adhered to a 0.1-m-wide, 1-mm-thick rubber sheet using tape. Note that the newly employed 4.8-m-long SMF (0.8–5.6 m) had a slightly lower BFS (~10.8 GHz) than that of the 12-m-long SMF (5.6–17.6 m). A mechanical wave was manually generated (Figure 9f) and propagated along the rubber-adhered section at a relatively slow speed. The sampling rate of the BFS (or strain) was set to 100 kHz, and the repetition rate of the distributed measurement was set to 100 Hz. Averaging was performed 10 times. The measurement range d_m was ~20.4 m (f_m swept from 5.048 to 5.153 MHz; 24th correlation peak) and the nominal spatial resolution Δz was ~0.39 m ($\Delta f = 0.5$ GHz; the neighbourhood effect was not considered).

Figure 8 Example of the simulated BGSs. The black dashed curve is the simulated BGS for the FUT configuration '0-0-0' (refer to Supplementary Fig. S2 for the definition), and the red solid curve is that for '1-1-1'. The green dotted curve, which is the sinusoidal fit of the solid curve, becomes maximal at $\Delta f = 64.18$ MHz.
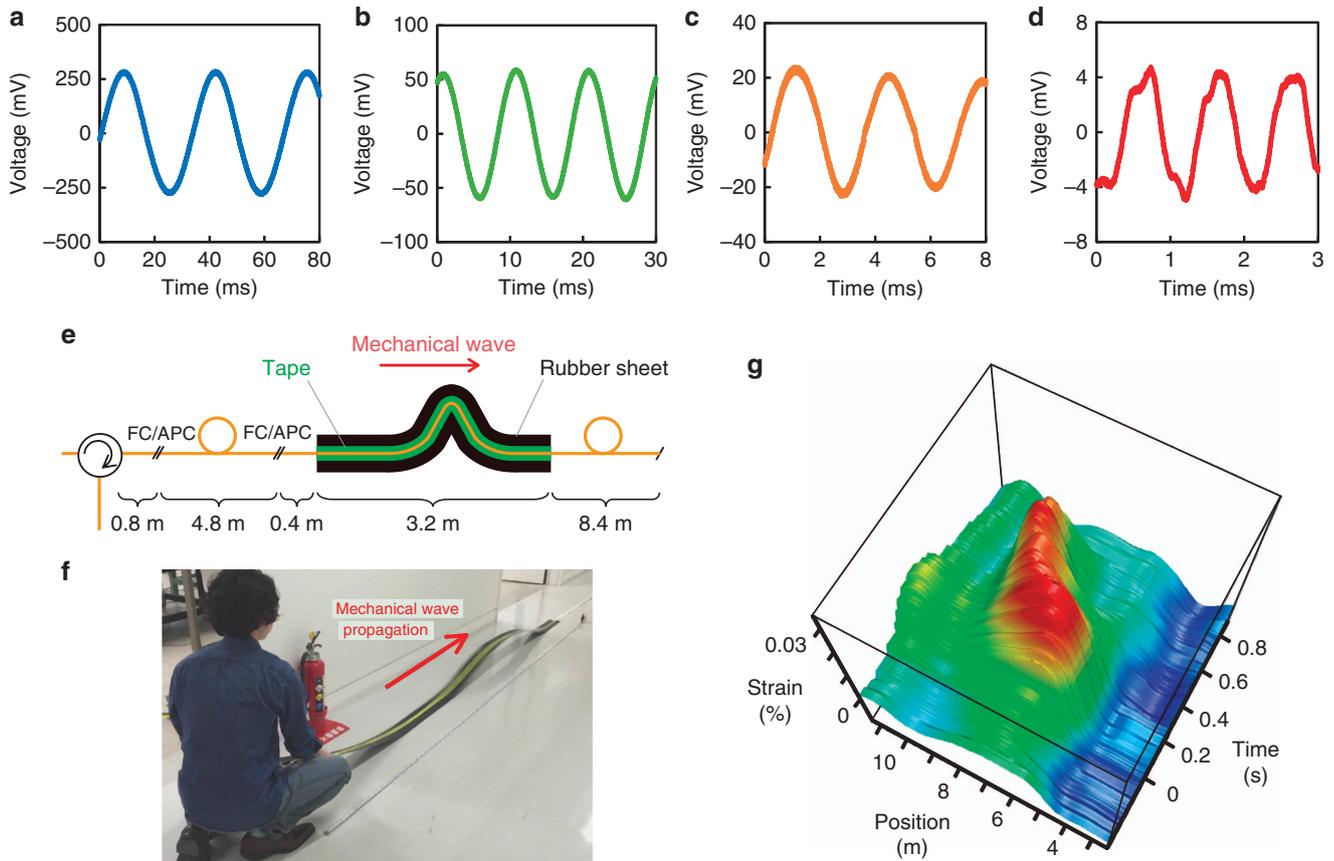

Figure 9 Ultrahigh-speed measurement results. Temporal variations (deviation from the initial value) of the output DC voltage when dynamic strains were applied to a 0.4-m-long section at (**a**) 30 Hz, (**b**) 100 Hz, (**c**) 300 Hz and (**d**) 1 kHz. (**e**) Schematic structure and (**f**) photograph of the FUT while tracking the propagation of a mechanical wave. (**g**) Measured temporal variation of the strain distribution.

The measured temporal variation of the strain distribution around the 3.2-m-long section attached to the rubber sheet (Figure 9g) shows that the mechanical wave propagation was detected, though the SNR was low. The propagation speed was calculated to be ~ 10 m s^{-1}. The length of the strained section and the amplitude of the strain decreased as the mechanical wave propagated, which is consistent with the actual observation (Figure 9f). The amount of strain caused by the wave propagation ($< 0.03\%$) seems to be valid, as it is close to that measured by two-end-access BOTDA[39]. The amount of strain along the 4.8-m-long SMF with a lower BFS was not correctly detected (negative values obtained), which is reasonable considering the operating principle that limits the measurable strain range. The negative-strain (i.e. compressed) regions, which should appear at the foot of the peak[39] were not clearly detected probably because of the combination of the following three reasons: (i) the dependence coefficient of the phase delay on negative strain (compression) was smaller, as the experimental setup was optimised for strain ranging from 0 to $\sim 0.2\%$; (ii) the low-pass filtering at the end of the signal processing reduced the drop of the voltage; (iii) the properties of the materials (rubber, tape and so on) used to fabricate the FUT were different from those in Ref. 39. In this way, although the SNR was not sufficiently high, the ultrahigh-speed distributed strain sensing capability of this system was demonstrated.

CONCLUSIONS

In this work, real-time distributed Brillouin reflectometry with intrinsic one-end accessibility and high spatial resolution was developed for the first time by use of a correlation-domain technique. In this configuration, the BGS was converted from frequency domain to time domain by mixing it with the output of a VCO. Then, the BGS in the time domain was approximated by a one-period sinusoidal waveform, and the BFS was converted into its phase delay, which was subsequently converted into a voltage so that the BFS information can be directly obtained. A strain sampling rate of up to 100 kHz at an arbitrary position was experimentally verified by detecting locally applied dynamic strain at 1 kHz. A repetition rate of distributed measurement of 100 Hz (10 times averaging, 100 sensing points) was also verified by tracking a propagating mechanical wave. We must admit that, compared with those of other high-speed techniques, including slope-assisted BOTDA[5,6] and BOCDA[19,20,25], the current performance of our method is low because of its major drawbacks, such as the relatively low measurement accuracy (in the worst case, approximately $+/-10\%$ error with 10 times averaging), spatial resolution degraded by a factor of ~ 3 (compared with standard BOCDR[30,31] or BOCDA[17]), and limited strain dynamic range (0 to $\sim 0.2\%$ in this experiment); these points could be a margin for improvement in the future. However, we anticipate that intrinsic one-end accessibility, the advantage of this system that other techniques cannot provide, will more than compensate for these shortcomings and that this will be a promising technique for distributed dynamic strain and temperature sensing with practical convenience, especially for a relatively short measurement range.

CONFLICT OF INTEREST

The author declare no conflict of interest.

Experimental setup

The 7 dBm (5 mW) output from the distributed-feedback laser diode (NX8562LB; NEC; ~1 MHz linewidth) was divided into two (pump and reference lights) using a 3 dB coupler. The pump light was led to a polarization scrambler (PCD-104; General Photonics) in order to suppress the polarization-dependent fluctuations of the BGS, amplified using an erbium-doped fibre amplifier (EDFA; HPA-200C-30-SM; Alnair) to 23 dBm (200 mW), and then injected into the FUT. The reflected Stokes light was amplified using another EDFA (LXM-S-21; Luxpert Technologies) to 3 dBm (2 mW) and mixed using a 3 dB coupler with the reference light that passed through a ~1 km long delay line. This optical beat signal was converted into an electrical signal using a photo detector (DSCR402; Discovery). For the electrical signal processing in Figure 1 in the main text, an amplifier (CA812-202; Ciao Wireless; 23 dB gain), a function generator (WF1946; NF Electric Instruments), a VCO (MAX2750EUA; Maxim), a dual channel programmable filter (3627; NF Electric Instruments), an ESA (R3273; Advantest), and an XOR logic gate in an integrated circuit (model 4046) were used. The ESA output was input to the computer via a sound board (XONAR U7; ASUSTek; 192 kHz/24 bit). An oscilloscope was virtually implemented in the computer using the freely available programming language Processing (https://processing.org/). For dynamic strain measurements of up to 1 kHz, a vibration generator (512-D; EMIC) and a laser Doppler velocimeter (CLV1000; Polytec) were used.

Simulation

The BGS in the correlation-domain techniques generally consists of two spectral components; one is the sharp signal peak corresponding to the strain, and the other is the sum of the noise substructure originating from all the other positions. Therefore, the strain distribution at the positions near the correlation peak may modify the overall shape of the BGS even when the peak frequency is kept unchanged. Thus, our phase-based method is susceptible to errors caused by the modification of the BGS because of the irregular strain distribution in the vicinity of the correlation peak. Here, we perform simulations to quantitatively evaluate this "neighbourhood effect" using the method detailed in Ref. S1.

The simulated configuration of the strain distribution in the vicinity of the correlation peak is depicted in Supplementary Fig. S2, where R is the theoretical spatial resolution calculated using Equation (2) and the arrow indicates the position of the correlation peak, i.e., the point of detection. For simplicity, we assumed that the length of the FUT is equal to the theoretical sensing range calculated using Equation (1), and that the BFS of the remaining fibre is constant ($\Delta v = 0$). The BFS at the point of detection was set to be unchanged ($\Delta v = 0$), while those of the nearby positions were changed ($\Delta v = +100$ MHz, corresponding to the maximal strain (0.2%) that can be detected with the simple configuration of this system). Figure 8 in the main text and Supplementary Figs. S3a–S3i show the resultant BGSs with a frequency sweep range (Δf) of 800 MHz (–400 to +400 MHz). The vertical axis was normalized so that the peak power with the uniformly non-strained FUT became 1. Considerable variations were observed in the shape of the BGS, while the gain peak frequency was not changed ($\Delta f = 0$). We then performed sinusoidal approximations to each simulated BGS, using the data in the frequency range of 360 MHz (–130 to +230 MHz; same as that in the experiments). The approximated curves and their peak frequencies are also presented in Figure 8 in the main text and Supplementary Figs. S3a–S3i. From these results, we can conclude that if an absolute error of +/–200 µε (or +/–10 MHz) is allowed, the spatial resolution is effectively lowered by ~3 times. We should note that the performance deterioration depends on the measurement parameters, such as the frequency sweep range, FUT length, and applied strain distribution. This conclusion will be a universal guideline which is also useful for other spectral-shape-based correlation-domain techniques[S2].
